A novel design of vibratory stimulation training system was developed in this study. Each participant took a pre-test, before receiving treatment with 20 seconds of vibratory stimulation (VS) at a specific frequency and amplitude. The participants then took a post-test. Percentage improvement was then calculated by comparing the pre- and post-test values for each index. The experimental data were analyzed through a two-way repeated-measures ANOVA analysis, with the independent variables being vibratory frequency and amplitude and the dependent variables being EMG root mean square, maximal force, rate of force development, and average force. The optimal vibratory stimulation pattern was found from this study that being a 60% maximal force loading combined with VS at 2.5 Hz and 1 N amplitude sustained over 20 s.

KEYWORDS: strength training, design, force, vibration.

INTRODUCTION: Strength training can be used to enhance sports performance, promote good health, and improve quality of life. There are many types of strength training, including resistance training, plyometric drills, and vibratory training. A number of recent studies have suggested that vibratory training can enhance training effects with a higher degree of safety (Trans, Aaboe, Henriksen, Christensen, Bliddal & Lund, 2009). The vibratory platform is designed to provide the athlete with an unstable environment and produce vertical excitation. This stimulates the muscle spindle, enhancing circulation and relieving muscle tension. Over the last 20 y, research has suggested that vibratory training can increase muscle power and improve competition performance (Giorgos & Elias, 2007). Most types of vibratory training use whole body vibratory training (WBVT) and it can be a useful modality as applied during the pre-competition warm-up (David, Holmes & Eric, 2008). Furthermore, WBVT has been linked to improved muscle strength in the lower extremities, muscle power, and jump height (Rittweger, Just, Kautzsch, Reeg & Felsenberg, 2002). Human bodies contain large amounts of damping tissue, which decreases the effects of vibration on the upper extremities. Improved muscle strength in this area contributes to improved sports performance and lower risk of injury.

There are two disadvantages in the existing vibratory mechanisms. First, they may potentially produce unsmooth signal profiles that may harmful to the trainees; and, second, they are unable to accurately control the frequency and amplitude of the force profile (Hsu & Tu, 2006). To address this problem, a novel design of vibratory stimulation training system (VSTS) which can provide precisely controlled smooth force profile to the trainee was introduced. The acute effect on the non-dominant upper arm elbow joint flexor was investigated experimentally.

METHODS: The participants were 14 healthy male college students (22.05 ±1.2 y; 62 ±3.4 kg; 170 ±4.7 cm), who had not experienced any upper arm injury or disease in the previous six months. All the experiments conducted in this project have been approved by the Research Ethics Committee of the National Pingtung University of Education. The designed VSTS consists of a pay load set, an AC servo-motor (GYS401DC2-T2A, Fuji Electric, Japan), a reduction gear set (SB090-L2-25, USC Motion Inc., Taiwan), a torque sensor (RT-50, Cap 50 Nm, JIHSENSE, Taiwan), a motor driver and a force controller (Figure1). With this system, the total force applied to the participants included two parts: an offset afforded by the pay load and the vibratory force with precisely controlled frequency and amplitude provided by the servo-motor through the reduction gear set. The force controller was basically a proportional-integral (PI) controller which controls the amplitude of the vibratory
force to follow the command values by use the feedback signal from the torque sensor. With the feedback force control system and the fact that the servo-motor can offer smooth sinusoidal force pattern, the load to the participants can be expected to be smooth and precisely controlled. An EMG sensor (biovision, D-61273, Wehrheim, Germany) and a force sensor (TEDEA, MODEL614, 1200 Hz, 50-300 Kg) were used for the tests. These two sensors were synchronized by a personal computer via the Labview system (NI, American).

Each participant took five different vibratory stimulation treatments, each day consisted of one treatment. There were five groups in this study, which consisted of different treatments and a control group. These were randomly assigned. First, the participants completed a series of 10-minute warm-up exercises. After warm-up, the participants took a pre-test for their non-dominant arm to obtain the related parameter as described below. Then, they received 20 s of vibratory stimulation, with specified values of payload (60% pre-test maximal force), different amplitudes and frequencies of the vibratory force. Finally, the participants were subjected to post-test to investigate the acute effect of the designed vibratory stimulation system on the non-dominant upper arm elbow joint flexor.

In this study, the participants were randomly assigned to one of the following treatments: high frequency high amplitude (HfHa, 30 Hz, 5 N); high frequency low amplitude [HfLa, 30 Hz, 1 N]; low frequency high amplitude (LfHa, 2.5 Hz, 5 N); low frequency low amplitude (LfLa, 2.5 Hz, 1 N); and a control treatment. The indices for evaluating the acute effect include root mean square of EMG (EMG$_{rms}$), maximal force (F$_{max}$), average force within 5s (F$_{ave}$), and rate of force development in 0.5 s (RFD$_{0.5s}$). Furthermore, the index used for evaluating the percentage improvement contributed by the vibratory stimulation was calculated by eq.[1]:

$$I = \frac{V_{post-test} - V_{pre-test}}{V_{pre-test}} \times 100\%$$

- $V$ - stands for the variables just defined.

On finishing the tests, the recorded data were analyzed using two-way repeated-measures ANOVA, with a significance level of $\alpha$=.05. The independent variables were vibratory frequency and amplitude (five groups). Dependent variables were EMG$_{rms}$, F$_{max}$, RFD$_{0.5s}$, and F$_{ave}$.

**RESULTS:** The results of this study are shown in Figure 2.

**EMG$_{rms}$:** Following vibratory stimulation, ANOVA results showed a significant difference in EMG$_{rms}$ rates between pre- and post-vibratory stimulation (n=14, F=2.900, p=0.031). The test result indicated that the EMG$_{rms}$ rates for HfHa, HfLa, LfHa, and CON were significantly higher than for LfLa (p<.05). Except the LfLa group, the EMG$_{rms}$ rate are positive, it showed...
that the LfLa stimulation treatment can activate the muscle group effectively than other stimulation treatment types.

**Fmax:** The stimulation treatments can elevate maximal contraction force of biceps brachii. Following vibratory stimulation, the ANOVA showed a significant difference in Fmax rates between pre- and post-vibratory stimulation ($F=3.439$, $p=0.014$). The test result indicated that the Fmax rates for HfHa, HfLa, LfHa, and CON were significantly lower than for LfLa ($p<.05$).

**Fave:** The stimulation treatments can elevate average contraction force of biceps brachii, and the value of LfLa group was higher than the other groups. Following vibratory stimulation, the ANOVA showed no significant difference in Fave rates between pre- and post-vibratory stimulation ($F=2.038$, $p=0.103$).

**RFD0.5s:** Except for the CON group, the RFD0.5s rate was positive. Following vibratory stimulation, ANOVA showed a significant difference in RFD0.5s between pre- and post-vibratory stimulation ($F=2.566$, $p=0.049$). The post-hoc test indicated that the RFD0.5s rates for LfHa and LfLa were significantly greater than for CON ($p<.05$).

---

**DISCUSSION:** A comparison of the acute effects of different types of vibratory stimulation showed that LfLa vibrated stimulation increased explosive contraction muscle strength (RFD0.5s =17%, Fmax =15%). There has been no effect on Fave but its rate had 10% increase, after LfLa vibrated stimulation. Stimulation at a frequency of 2.5 Hz with amplitudes of 5 N and 1 N enhanced explosive force, but stimulation at a frequency of 30 Hz with amplitudes of 5 N and 1 N did not achieve the same result. This demonstrated that stimulation frequency is the dominant factor affecting the study outcome. Previous studies have indicated that high frequency vibratory stimulation can enhance elite athletes’ acute maximal force in the lower extremities (Mester, Spitzen, Schwarzer, & Seifriz, 1999) and explosive force in the upper extremities (Bosco, Cardinale, & Tsarpela, 1999). In this study, the participants, who were healthy college student, received vibratory stimulation at a lower frequency, which allowed for gains in explosive force while minimizing fatigue. In the tonic vibratory reflex [TVR] the muscle belly or tendon is stimulated by the $\alpha$ afferent neuron. The TVR is transmitted to the spindle by the $\alpha$ motor neuron, activating the fiber. This muscle-neural phenomenon can be examined using EMG analysis. Following 20s of vibratory stimulation in the upper extremity at a frequency of 2.5 Hz and amplitude of 1 N, the EMGrms index decreased by 8%. Other related studies have shown similar results. For example, Bosco et al. (2008) found that 60 seconds of vibratory stimulation raised the EMG mean power frequency, but decreased the
EMGrms of the biceps brachii. Vibratory stimulation can activate α motor neuron through TVR and enhance nervous system adaptation (Romaiguere, Vedel, Azulay, & Pagni, 1991). Activation of the nervous system can elevate neuronal firing frequency and increase the synchronized neuronal units. The optimal level of vibratory stimulation loading can improve muscle adaptation, and decrease activation to avoid loss of muscle strength. This can improve effectiveness of muscle group. Overall results showed that low frequency and low amplitude vibratory stimulation (LfLa; 2.5 Hz, 1 N) which by the vibratory stimulation system of this study can have benefits for participants’ muscle strength and maximal force in the biceps brachii. This study showed that 60% maximal force loading, combined with vibratory stimulation at a frequency of 2.5 Hz and amplitude of 1 N sustained over 20 s, was the best acute vibratory stimulation for the flexor muscle of the elbow joint.

CONCLUSION: This study presents a well-designed system and the associated methodology for examining the acute effect of vibratory stimulation on elbow joint flexor performance. An optimal vibratory stimulation pattern has been found with the most significant acute effect in terms of explosive contraction muscle strength and maximal force. For practical applications, because the VSTS can provide with smooth, precisely controlled frequency and amplitude of vibratory force, it is safe and comfortable for the athlete. Furthermore, the results provide a method in finding an optimal vibratory stimulation pattern for an athlete in warm up exercises to enhance his/her sports performance.
